Abstract

This report consolidates the current state of the ICAIF working into a single evidence-grounded narrative. The research began as a broad multimodal earnings-conference-call (ECC) prediction project, but it has progressively narrowed into a cleaner empirical question: under noisy timing, can after-hours conference calls explain or predict the *incremental* volatility shock that remains after accounting for pre-call market conditions? Current empirical evidence suggests an affirmative answer, albeit within a strictly constrained and qualified context. The current robust core is a clean `after_hours` setting with target `shock_minus_pre`, strong market-aware baselines, and a narrow signal combination built from `A4` observability/alignment and compact `Q&A` semantics. The strongest transferability is no longer about adding more routing complexity, but about *reliability-aware abstention*: local semantic corrections should be used when agreement is strong and deferred when the market baseline is safer. The newest exploratory branch further suggests that the single hardest analyst question may carry a sharper local signal than the full exchange, especially when represented as a compact, non-structural, question-centric semantic view. This document summarizes the data assets, target design, pipeline, benchmark logic, major empirical findings, negative results, current contribution hierarchy, and the decision gate for the next research phase.

1 Introduction

Fundamentally, the project studies whether text [2, 6], timing, and audio [7] information from earnings conference calls can explain or predict high-frequency market reactions. However, the project has undergone a substantial conceptual pivot. Early versions were framed as a generic multimodal prediction exercise. The current version is much narrower and more more financially rigorous. Instead of trying to predict raw post-call volatility levels, the research now frames the task around `shock_minus_pre`, a residual-style outcome designed to isolate the call-related component of the post-call volatility response.

This reframing matters because conference-call prediction is fraught with methodological pitfalls. A model can exhibit inflated performance simply by learning that some firms are always more volatile than others [4], that some event types cluster in certain periods, or that regular-hours calls occur within a noisier information environment. A large part of the research's progress stems not from deploying more complex architectures, but from learning how to systematically mitigating these confounding factors.

Table 1: Observed data coverage and usable panels in the current repository. Counts come from the current manifest and built panels.

Asset	Raw count	Currently usable count
A1 transcript JSON files	2146	2133 parsed event keys
A2 transcript HTML files	842	722 pass / 114 fail
A3 audio files	796	796 linked event keys
A4 alignment CSV files	671	670 parsed event keys
5-minute stock files (D)	25 tickers	25 / 30 DJ30 tickers
Event target table	553 rows	553 usable event rows
Modeling panel	553 rows	553 joined rows
Clean after-hours subset	172 rows	172 aligned rows

This report has two goals. First, it documents the actual current state of the research in a form that can support stage evaluation, advisor discussion, and future writing. Second, it freezes a hierarchy: what the mainline is, what the most credible secondary method contribution is, and what remains exploratory but worth preserving.

As of March 23, 2026, the study establishes three main takeaways. First, the fixed-split mainline is stable: under noisy timing, clean `after_hours` calls contain usable incremental ECC signal, and the cleanest evidence points to `A4` plus compact `Q&A` semantics. Second, the findings regarding model transferability has become much cleaner: the strongest reading is *reliability-aware abstention*, not greater router complexity. Third, the hardest-question investigation is now a meaningful exploratory finding: the single hardest analyst question appears to carry a real local signal, especially in a compact non-structural representation, although this investigation remains too narrow to replace the mainline.

2 Data assets, integrity constraints, and target design

The research is built on the DJ30 package shared for the course project and later research extension. The core assets are `A1` transcript JSON, `A2` transcript HTML, `A3` audio, `A4` timestamp alignment, analyst-side controls from `C1/C2`, and 5-minute market data in `D`. What matters most for the current research is not merely that these assets exist, but how incomplete or noisy they are.

Table 1 shows the research-level picture. The raw DJ30 package is sizable, but the usable research core is much smaller. The current event target table, modeling panel, and event-level feature table

all cover 553 rows. The matched clean `after_hours` subset used by the aligned-audio and hardest-question branches contains 172 rows. The A2 integrity summary also matters: 722 HTML files pass the current integrity check, 6 are warnings, and 114 are fails. In addition, the market-data side still covers only 25 of the 30 DJ30 names, with `CRM`, `CVX`, `PG`, `TRV`, and `V` still missing from `D`.

Two data-quality constraints shape almost everything else in the research. First, `A2` is not a definitive temporal ground truth. It contains scheduled times rather than guaranteed actual call-start times. Second, `A4` is useful but noisy. It is best treated as observability or alignment supervision, not as perfect timestamp truth. A useful mental picture is that the repo is trying to understand a conversation through fog: `A4` is not a perfect GPS trace, but it is still far better than pretending that the fog does not exist.

Those constraints directly motivate the target redesign. The research no longer treats raw post-call realized volatility [1] as the cleanest main outcome. Instead, the canonical target is now

$$\texttt{shock_minus_pre} = \texttt{post_call_60m_rv} - \texttt{pre_60m_rv}. \quad (1)$$

This shifts the question from "which firms have high volatility?" to the much more relevant question "what extra volatility shock remains after the pre-call baseline is accounted for?" The resulting setup is narrower, but also more credible.

3 Pipeline and evaluation philosophy

The research now follows a fairly disciplined build pipeline. File manifests and QC scripts verify data availability and filter for usable files and which files are usable. Target-construction scripts turn 5-minute market bars into event-level before/during/after-call outcomes. Panel-building scripts merge transcript, timing, analyst, QC, and target information into a modeling table. Feature-building scripts then create event-level text, timing, audio-proxy, real-audio, and Q&A benchmark features. Finally, a comprehensive suite of benchmark and ablation scripts tests target variants, timing subsets, priors, residual models, multimodal additions, transfer settings, and exploratory local-signal branches.

The evaluation philosophy is equally important. Three design choices now define the empirical style of the research.

- **Strong priors first.** The point is not to beat a weak baseline. The point is to test whether ECC-related features add value on top of a credible market-aware prior.
- **Residual prediction rather than naive pooled prediction.** The current mainline explicitly tries to explain the residual component of the event-level response.
- **Subset discipline.** The paper-safe main setting is not "all calls." It is off-hours, especially clean `after_hours`. This is a narrower but better-defined information environment.

That philosophy is why the research's best results are not just a matter of architecture choice. The strongest gains came when the task definition, sample definition, and evaluation discipline were made more honest.

4 The fixed-split mainline: where the current core result comes from

The corrected off-hours benchmark provides the broad anchor for the research. On clean corrected off-hours rows, the prior-only model reaches only about $R^2 \approx 0.198$, whereas the structured residual core reaches about $R^2 \approx 0.913$. This is an important result because it demonstrates that the corrected target is not trivial and that the repo's residual framing is empirically meaningful.

Table 2: Core fixed-split results on the clean `after_hours` line.

Model	Test R^2
Prior only	0.0351
Pre-call market only	0.9174
Pre-call market + controls	0.9194
Pre-call market + A4	0.9014
Pre-call market + A4 + compact Q&A	0.9271
Pre-call market + controls + A4	0.8968
Pre-call market + controls + A4 + compact Q&A	**0.9347**

The narrower and more paper-safe mainline, however, lives in clean `after_hours`. Table 2 shows the canonical fixed-split ladder.

Several things are worth emphasizing here. First, strong pre-call market information already explains a large part of the variation, with `pre_call_market_only` reaching about 0.917 on the test split. Second, controls alone add very little, pushing the result only to about 0.919. Third, the step from `A4` to `A4 + compact Q&A` is where the most credible additional gain appears. The move from `pre_call_market + A4` to `pre_call_market + A4 + Q&A` has a paired permutation $p(\text{MSE}) \approx 0.002$. The move from `pre_call_market + controls + A4` to `pre_call_market + controls + A4 + Q&A` remains positive with $p(\text{MSE}) \approx 0.012$.

The strongest fixed-split line therefore is not a generic multimodal story. It is a much narrower claim: under noisy timing, the most credible incremental ECC signal currently comes from `A4` observability/alignment and compact `Q&A` semantics [5, 8] on top of strong pre-call priors.

Figure 1 makes the structure more visual. The left panel shows the mainline ladder. The right panel highlights a second important conclusion: once the A4-centered branch is isolated, compact Q&A semantics survive, while sequence-heavy additions do not. The A4 extension benchmark shows

- `controls + A4 + Q&A`: $R^2 \approx 0.9347$,
- `controls + A4 + role sequence`: $R^2 \approx 0.8409$,
- `controls + A4 + weak sequence`: $R^2 \approx 0.8657$.

In short, the current research has fairly strong negative evidence against the idea that heavier sequence structure is the right next step. The gain appears to come from disciplined signal isolation, not from more sequence machinery.

5 Extensions that helped, helped conditionally, or failed

One reason the research is now healthier is that it has accumulated enough negative evidence to stop treating every new branch as a candidate headline.

The audio branch is a good example. The research did not simply discover that "audio helps." It discovered something narrower and more useful. Raw aligned audio is too noisy, and the old coarse

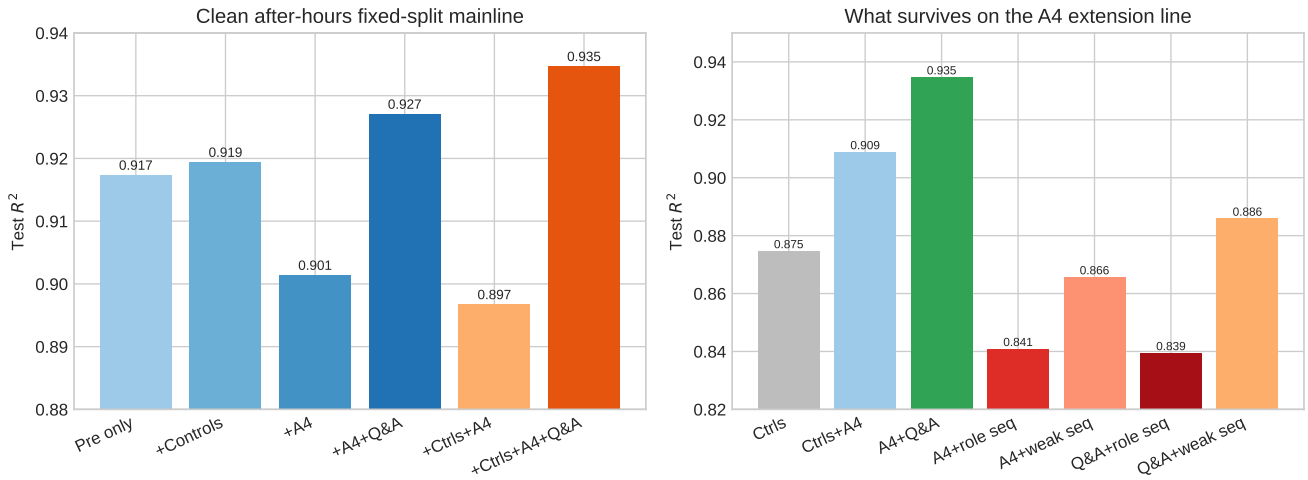

Figure 1: Left: the clean `after_hours` fixed-split ladder. Right: the A4 extension branch. Compact Q&A semantics survive; sequence-heavy additions do not.

audio proxy is worse still. But compressed aligned audio can help on some branches. On the clean after-hours line,

- `pre_call_market + controls`: $R^2 \approx 0.9194$,
- `+ aligned_audio_svd8`: $R^2 \approx 0.9247$.

The same compression also helps on the controls-plus-A4 branch. However, once the strongest semantic mainline is restored with `lsa=64`, the same story no longer holds: `controls + A4 + Q&A` remains at about 0.9347, while adding aligned-audio SVD lowers the result to about 0.9274. So audio is not worthless, but it is not the main contribution either.

Role-specific text provides another illustrative case. The research tested whether analyst-question or answer-side semantics should replace pooled Q&A semantics in the mainline. They do not. Question-role semantics are distinct, but not mainline-additive. Specifically, replacing pooled Q&A with question-role features degrades performance; stacking question-role features on top of pooled Q&A yields inferior results; and residualizing question-role features against pooled Q&A further exacerbates the decline in predictive accuracy. That is a useful result because it clarifies the boundary between a signal that is scientifically interesting and a signal that belongs in the core predictive stack.

Table 3 summarizes a set of branches that were informative but should no longer be treated as headline candidates.

This table is not just housekeeping. It is part of the contribution. The repo now knows much better what should remain center stage and what should become appendix or bounded extension material.

6 Transfer and generalization: from complexity search to abstention

The transfer side of the research evolved a great deal. Earlier rounds explored observability gates, event routers, conservative override rules, signal-family searches, complementary experts, and consensus schemes. In hindsight, that search was useful because it led to a cleaner conclusion: the strongest transfer story is not "we found a very clever router." The strongest story is that transfer-side local corrections are conditionally credible and should be used with restraint.

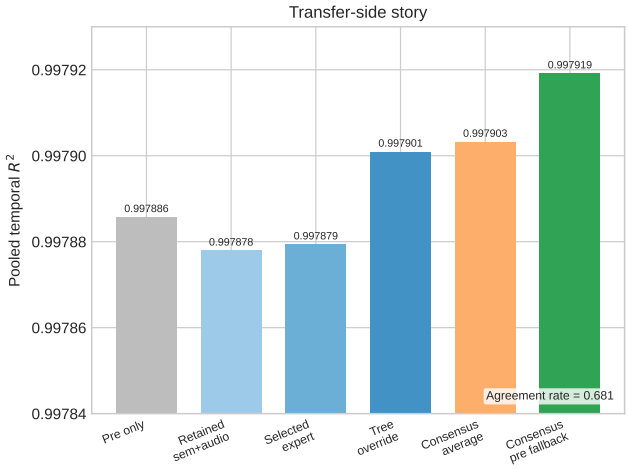

Figure 2: Pooled temporal transfer routes. The strongest stable reading is now abstention-based rather than complexity-based.

The pooled temporal transfer benchmark makes this visible. The best current pooled route is a consensus-style fallback to the market baseline, with $R^2 \approx 0.997919$. This is only slightly higher than the strongest simpler alternatives, but the interpretation is much better. The model uses local information when the retained signals agree, and it abstains when disagreement suggests that the local correction is not trustworthy enough.

Figure 2 visualizes the transfer-side consolidation. The best route does not dramatically dominate all alternatives, and that is precisely why the interpretation must stay disciplined. The repo does *not* currently support a claim that semantic or audio transfer uniformly

Table 3: Selected branches that were informative but did not survive as current headline candidates.

Branch	Stronger reference	Branch result	Current reading
Role sequence on clean A4 line	A4 + Q&A = 0.9347	A4 + role seq = 0.8409	Not retained
Weak sequence on clean A4 line	A4 + Q&A = 0.9347	A4 + weak seq = 0.8657	Not retained
Compressed aligned audio on semantic line	Ctrls + A4 + Q&A = 0.9347	+ audio SVD = 0.9274	Side-branch only
Question-role stacking on mainline	Ctrls + A4 + Q&A = 0.9347	+ question role = 0.9294	Not mainline-additive
Question-role residual on mainline	Ctrls + A4 + Q&A = 0.9347	+ question resid = 0.8877	Residual hurts
Hardest-answer local view	Hardest question = 0.998655	Hardest answer = 0.998551	Question-centric signal
Top-1 Q&A pair local view	Hardest question = 0.998655	Top-1 Q&A = 0.998557	Fusion adds noise
Supervised question subspace	Question LSA = 0.998655	Best PLS = 0.998586	Less transferable

Table 4: Representative transfer-side routes from the pooled temporal benchmark and the later local hardest-question branch.

Route	Repr. R^2
Pre-call market only	0.997886
Retained semantic+audio gate	0.997878
Validation-selected transfer expert	0.997879
Consensus fallback to market baseline	0.997919
Hard abstention (latest-window local shell)	0.998636
Hardest-question non-structural LSA(4)	**0.998655**
Question supervised compact subspace (best PLS)	0.998586

beats the strongest market baseline across ticker-held-out and temporal slices. What it does support is a narrower claim: *reliability-aware abstention is the cleanest current transfer-side method reading.* That is a more honest contribution than pretending that a slightly more complicated router has already solved transfer.

This matters for stage evaluation. Transfer is no longer a free-for-all search for one more clever model. It has a stable interpretation, even if the effect sizes remain modest.

7 The hardest-question branch: the strongest exploratory signal in the repo

The newest and most interesting exploratory branch shifts attention from the full exchange to a local object: the single hardest analyst question [3]. The branch began as a question about whether the most difficult local pair in a call might carry sharper information than the whole conversation. It has since become much more specific.

The first striking result is that the strongest local route is already fairly compact. The hardest-question LSA(4) bi-gram view reaches about $R^2 \approx 0.998655$ on the latest held-out window, slightly above the hard-abstention shell at about 0.998640, with paired $p(\text{MSE}) \approx 0.044$. This is a small effect, but it is one of the first exploratory local signals in the research that clears the current hard-abstention reference on a held-out slice.

The second important result is about what this signal is *not*. Structural or strategic probe vocabulary does not appear to drive it. When structural-probe phrases are masked out, the strongest route is unchanged down to the pooled metrics. Similarly, adding the hardest answer or the top-1 local Q&A pair does not help. In fact, both hurt. This means the exploratory signal is not simply "more local context." It is much more specifically *question-centric.*

The third result concerns representation. Small supervised subspaces, such as PLS-based question encodings, underperform the compact unsupervised representation. That suggests that, at the current matched-sample scale, the supervised compression is more prone to overfitting phrase pockets that do not transfer as cleanly.

Figure 3 summarizes the branch. The left panel shows that the local signal is real but still narrow. The right panel shows its structure. The masked question view remains strongest; the answer-only and Q&A-pair views are weaker; the compact clarificatory lexical factor partially recovers the signal; and the supervised question subspace fails to replace the unsupervised masked-question encoding.

This branch is therefore best read as an exploratory signal discovery, not as a replacement for the mainline. The repo now has evidence that the single hardest analyst question may carry a local cue that survives structural masking and does not benefit from broader local fusion. That is scientifically interesting, but it is still too narrow to displace the main fixed-split story.

8 Stage evaluation: what is locked, what is bounded, and what is next

At this stage, the research supports a fairly clear hierarchy.

Locked mainline. The paper-safe core is now clear. It is the clean `after_hours` setting, the `shock_minus_pre` target, strong pre-call market priors, and a narrow signal stack built from `A4` plus compact Q&A semantics.

Secondary method contribution. The transfer-side method story is also coherent enough to lock as secondary rather than primary: reliability-aware abstention is the most defensible current interpretation of the transfer experiments.

Exploratory but retained branch. The hardest-question line is worth keeping because it discovered a real local signal. However, it should remain explicitly exploratory. It is strongest when represented as a compact, non-structural, question-centric semantic view. It is not yet broad enough to supersede the primary analytical framework, and it should not be inflated by reintroducing more shell complexity.

Demoted paths. Heavy sequence modeling, generic multimodal stacking, audio as headline, and growing router complexity for its own sake are now demoted. This is not a weakness. It is a sign that the research has become selective.

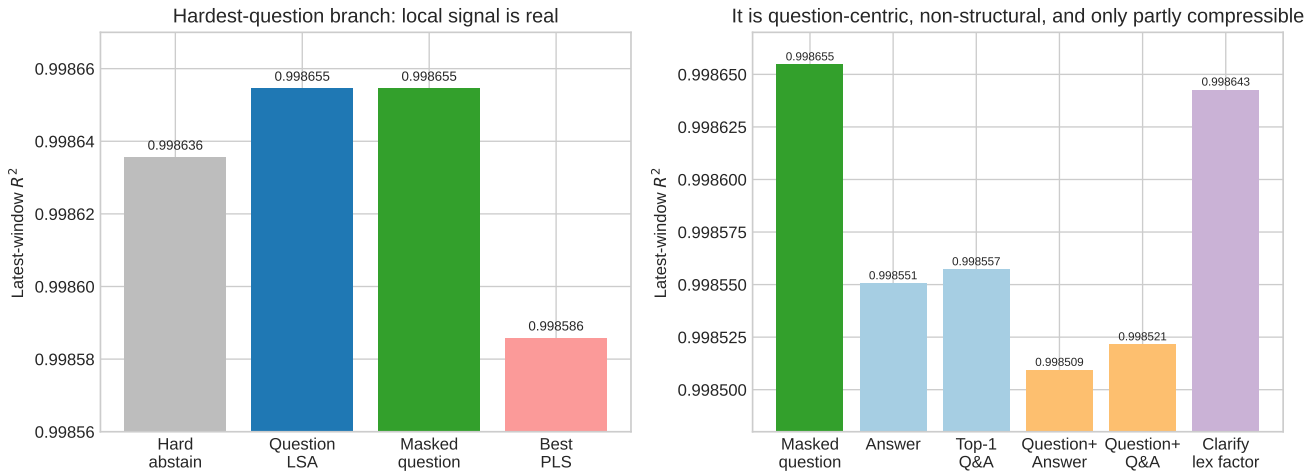

Figure 3: Left: the main latest-window hardest-question comparison. Right: evidence that the signal is question-centric, non-structural, and only partly compressible.

If we had to evaluate the project today, the fairest verdict would be the following: *the project is viable, it has a credible mainline, and it is no longer in uncontrolled exploration; but it is also not yet in final paper-freeze mode.* The right stage label is something like *consolidated mainline plus selective high-value extension phase.*

9 Limitations and next-phase gate

Recognizing the limitations of this study is as critical as highlighting its positive empirical results. First, this is still a DJ30 pilot-scale setting. Many results are directionally informative but not yet broad enough for strong external-validity claims. Even the strongest findings are still based on a relatively limited event universe, while the matched clean `after_hours` subset is smaller still.

Second, the transfer-side gains are coherent but modest. These improvements must not be overstated. The reliability-aware abstention framework is cleaner and more defensible than the earlier approaches relying on routing complexity, but it is still a bounded extension rather than a dominant headline result. Third, the hardest-question branch is a local mechanism, not yet a mature method family. It is one of the most interesting exploratory findings in the research, but it remains narrower than the main fixed-split contribution.

Fourth, the research still lacks large-scale replication beyond the pilot regime, which remains the biggest structural gap between a strong pilot study and a robust submission package. More broadly, the project is currently stronger as a disciplined research program than as a fully consolidated methods paper. That is acceptable for a stage report, but it also means the next phase should focus on consolidation rather than renewed expansion.

These limits naturally imply a gate for the next phase. The project should not go back to broad exploration. It should choose between two disciplined next moves:

(1) a confirmation-and-scale phase, which strengthens the mainline through broader replication, stronger robustness packaging, and more formal benchmarking; or
(2) a tightly controlled extension phase, where only one exploratory branch is allowed to deepen further, with the hardest-question line currently the strongest candidate.

10 Conclusion

The current evidence supports a credible core empirical framework under noisy timing. The clean `after_hours` line remains the most stable result, the transfer-side interpretation is now more coherently framed around abstention rather than complexity, and the hardest-question branch has emerged as a bounded but genuinely interesting exploratory signal.

Taken together, the research has moved beyond broad exploration and toward a clearer internal hierarchy. The main task for the next stage is therefore not to open many new directions, but to reinforce the existing structure through confirmation, consolidation, and selective follow-up.
